## ABSTRACT

This thesis assesses the methodology and input sensitivity of the Method of Screening Operational Concepts of Warfare (MOSCOW) model. This assessment illuminates the fundamental assumptions underlying the model's methodology and evaluates the model's sensitivity to small percentage changes of inputs. Results provide an estimate of MOSCOW's limitations, suggesting which parts of the model may need to be improved.

## I. INTRODUCTION

Recent research conducted by the RAND Corporation for the U.S. Army has resulted in the development of a new low resolution land combat model. This model, Method of Screening Operational Concepts of Warfare (MOSCOW), is designed to allow users to evaluate the differences between various war fighting concepts. Briefly stated, this model uses a Lanchesterian square law formulation to compute the quantity of Blue force resources required to secure a specified attrition of Red forces in a given combat scenario. The central features of the model are described in RAND report R-3643-A, A New Approach for the Design and Evaluation of Land Defense Concepts. This report provides a brief explanation of the model's general methodology and how such a model can be used to aid in war fighting concept analysis.

The traditional aim of land combat modeling is to answer the question, "Who will win the Battle?" The approach used to answer this question usually combines knowledge of a battle's initial conditions (force levels, doctrine, weapons' characteristics), the attrition relationships between weapons, and, for each side, the set of conditions or condition that constitutes losing. The Vector-In-Commander model, currently the Army's primary modeling tool to address force analysis issues, uses this approach. MOSCOW, by contrast, attempts to

answer the question, "How much friendly force is needed to win?" To accomplish this, MOSCOW combines information about a specific scenario with a description of the combat capabilities of an individual friendly combat unit. Scenario information includes the size, organization, and weapons characteristics of the opposing force, effects of the environment and terrain, and the attrition relationships between enemy and friendly weapons. Friendly forces are described only in terms of an "average" combat unit. Such units are typically one or two echelons smaller than the total size of the opposing force. MOSCOW uses this information to determine the number of such friendly units required to destroy a sufficient quantity of the opposing force to produce victory. Victory is defined as the amount of attrition which friendly forces must impose on the enemy.

In its current version, MOSCOW has several desirable features. First, it is implemented as a LOTUS 1-2-3 spreadsheet. Entering or modifying any of the approximately 350 input parameters, running the program, or capturing the results of model runs requires a personal computer and a minimum of experience with LOTUS. Model run time is on the order of seconds. Most favorable, however, is the intuitive appeal of the model's output which simply lists the amount of resources needed for the friendly, or Blue, force to accomplish its tactical objective. The advantage of this approach is that it allows for simple comparisons between

different sets of model inputs. Where one set of inputs may, for example, require nine friendly units to achieve victory, another set may require ten. Thus, MOSCOW's outputs can be easily ranked, allowing the most favorable (e.g., those requiring the fewest resources) to be immediately identified. An example of the output screen produced by the current version of MOSCOW is shown in Table 1. This example was

produced by inputs representing the defense of Europe.<sup>1</sup> In this situation, friendly units are measured in terms of divisions (approx. 1400 combat vehicles) and the success objective is defined as the destruction of 80% attacking enemy divisions (each enemy division contains approximately 1100 combat vehicles). Note that this output is divided into three parts. The first part reports the total friendly force requirements needed to achieve success. The second part summarizes total logistic and personnel cost. The last section is a report of the average daily logistic and personnel cost. The "delay" output measures the additional time enemy forces will need to achieve a specified penetration into friendly territory due to combat with friendly units. This penetration limit may be seen as the enemy force objective. In this example, the penetration limit is 30 kilometers. An explanation of the many abbreviations used in Table 1 is in Appendix A.

Although this type of output substantially eliminates the need for data reduction or post-processing common to other higher resolution models<sup>2</sup> which rely on killer-victim score boards, sensitivity analysis requires multiple model runs.

---

<sup>1</sup> Table 1 shows an output screen for inputs proposed by Romero [Ref. 1] which depict a scenario for the defense of Europe using MOSCOW version MO031188. This paper investigates the performance of this version of MOSCOW.

<sup>2</sup> The Vector-In-Commander (VIC) model stands in stark contrast to MOSCOW in this regard.

This is required since MOSCOW's output is the result of completely deterministic calculations. The current version contains one method of recording the results of such experiments for later comparisons.

#### A. OBJECTIVE

The central aim of this paper is to provide an assessment of MOSCOW for use as a low resolution land combat model. This assessment is based both on an analysis of the general methodology used in MOSCOW and the results of experiments. These experiments explore model sensitivity by examining the difference in MOE's produced by various inputs. Results focus on MOSCOW's limitations and possible improvements.

#### B. SCOPE OF ANALYSIS

This analysis has two distinct parts. The first part is an investigation of MOSCOW's modeling methodology. This investigation indicates the circumstances in which underlying methodology may be incompatible with a potential combat scenario. The second part explores the sensitivity of the model to changes in a subset of fundamental input parameters. This exploration illuminates where the natural variability of inputs may produce instability or unexpected results. Such relationships are a point of concern in any model verification effort. These sensitivity experiments provide an initial look at model verification by illuminating obvious modeling errors.

## II. OVERVIEW OF MOSCOW'S METHODOLOGY

MOSCOW is a computationally complex model which ultimately represents a real battlefield by a series of simple battles between appropriate numbers of two different combat systems or forces. Consider a real world conflict between two sides, Red and Blue, where each combatant uses a large number of different types of direct and indirect fire systems. The first step in using MOSCOW is to quantitatively arrive at a set of input values which express not only the average lethality, mobility, vulnerability, and logistical attributes for both Red and Blue forces, but also incorporates the effects of morale, doctrine, terrain, and the synergism which may exist between weapons systems. This step is not trivial. Training and Doctrine Analysis Command, Ft. Leavenworth draft technical report, A Methodology for Estimating MOSCOW Inputs, proposes one method using harmonic averaging of weapon system and force characteristics to compute input value estimates<sup>3</sup>. Appendix B gives a brief description of the various types of inputs and lists two sets of unclassified inputs generated using this procedure. While this reference gives a complete description of specific inputs, the central feature of MOSCOW

---

<sup>3</sup> This report also discusses assumptions implicit to the input estimation process and provides two unclassified sets of inputs which depict a US Corps employing airland battle doctrine in both attack and defend scenarios on NORTHAG terrain.

is the simplicity of the methodology used to construct an attrition model. This model incorporates the contributions of direct fire weapons, indirect fire support means, and attacking aircraft (including helicopters and fixed wing).

#### A. FUNDAMENTAL ASSUMPTIONS IN MOSCOW

One important result of the input estimation process is the formulation of "average" combat vehicle attributes for Red and Blue. These values represent an abstraction from reality, expressing the operational attributes expected from a myriad of real weapon systems in a single vehicle. Another important result of input estimation is the aggregation of direct and indirect fire attributes of maximum range, rate of fire, and lethality. This is important since these quantities define the rate of attrition a force is able to inflict on its opponent during battle. Although the combination of both direct and indirect fire components in an attrition model can be modeled using a heterogeneous system of differential equations [Ref. 2], MOSCOW uses the following assumptions that:

1. The rate at which targets are susceptible to attack by indirect fire systems is constant throughout the battle.
2. For each side, the proportion of direct and indirect fire systems as a fraction of the total force remains constant throughout the battle.

These assumptions reduce a complex heterogeneous formulation to the simpler square law case<sup>4</sup>. The viability of these assumptions is not addressed in the existing description of MOSCOW's methodology<sup>5</sup>.

The simplification to a square law formulation has the advantage of an explicit solution [Ref. 2]. An alternative method would be to use a Helmbold formulation [Ref. 3] of the form:

$$dx/dt = -a (x/y)^{1-w} y \quad (1)$$

$$dy/dt = -b (y/x)^{1-w} x \quad (2)$$

This method would require a numeric solution and necessitate a significant programming effort to implement in the current version of MOSCOW<sup>6</sup>. Its advantage, however, is that the relationship between the direct and indirect portions

---

<sup>4</sup> Mathematical details of how this simplification works are in Appendix C.

<sup>5</sup> In fact, these assumptions are not directly discussed. Limitations suggested by Romero (section 4.2.1) indicate that MOSCOW is suited only to those situations where a sufficiently large number of units (at least 3 - 5) are in combat long enough to establish a relatively constant tempo of combat activities.

<sup>6</sup> Recoding would be required to replace closed form solutions of the square law formulation with a subprogram which calculates a numerical approximation. Since such methods typically require iterative calculation, incorporating this change in the current version of MOSCOW will be difficult because MOSCOW already requires a separate iterative procedure and only one such procedure can be explicitly coded into LOTUS.

of the battle can be examined directly by varying the parameter,  $w$ , which is an exponential scaling parameter. One way to obtain values for the attrition rate coefficients,  $a$  and  $b$ , is to aggregate the results of higher resolution models. In any event, setting  $w = 1$  reduces the formulation to the square law case while  $w = 1/2$  approximates the linear law case. However, Taylor, [Ref. 4] shows that estimating this exponential parameter is difficult for any given scenario. MOSCOW currently claims to provide a similar capability based on an exponential change in the form of the time dependent solution to the square law formulation [Ref. 1]. As shown in Appendix D, this change produces an attrition relationship which is not equivalent to the square law case. Not explained further by Romero, it is apparently a heuristic technique which can be used to change the pace of attrition.

## B. ACTIVITY CYCLE CONSTRUCTION

MOSCOW uses an activity cycle concept to describe the various related activities of Red and Blue forces. As expected, these activities are not symmetric between attacker and defender. Table 2 lists the fifteen activities used in the current version of MOSCOW.

**TABLE 2. List of MOSCOW Activity Cycle Events**

Defend Activities	Attack Activities	Common Activities
Prepare defenses	Move to wpn range	Survey and Reconnoiter
Defend	Attack (Initial)	Delay for orders
	Attack (Reinforced)	Disengage
	Reclose	Reconstitute
		Move to exchange point
		Load supplies
		Repair
		Rest
		Move to standby position

A potential criticism of this methodology is that it is ill suited to describe the combat processes of large organizations (corps/division) which are doctrinally committed to continuous combat operations. MOSCOW eliminates this problem by defining activity cycles in terms of the time an individual combat system can expect to spend in each activity event. This avoids the problem of trying to define the length of a division's attack event, or, with even greater absurdity, trying to decide on the distance an entire division must artificially travel to resupply even though such supplies are doctrinally brought forward to units in contact with the enemy.

#### C. AIR SUPPORT

MOSCOW uses a simple method to describe air support in a land combat scenario. This method avoids the use of a Lanchester type formulation by assuming that the attrition rate per sortie is constant. The total number of sorties flown is computed directly from user supplied inputs of the

total number of aircraft available, attrition rate per sortie, and the sortie rate<sup>7</sup>. Vehicle attrition which results from close air support (CAS) and air interdiction (AI) is assumed to be proportional to the total number of sorties flown.

To eliminate difficulties in linking the air and ground portions of the model, the initial numbers of Red and Blue ground combat systems are lowered by the attrition effects of air attacks during the entire battle<sup>8</sup>. Using these revised force levels, the attrition produced by ground combat is calculated using the square law relationships previously discussed. While this partition of attrition calculations obviously limits MOSCOW's capacity to model many possible methods of employing air support, the model provides a certain flexibility in that support can be partitioned between CAS and AI with further allocations to vehicle attrition, imposing delay, or disruption of enemy command, control, and communication capabilities.

#### D. HEADQUARTERS ARTILLERY

Although MOSCOW aggregates the effects of indirect fire systems into the direct fire battle by using the simplifying assumption detailed in Appendix C, the model attempts to account for counterbattery fire, artillery attacks on enemy

---

<sup>7</sup> See Appendix E

<sup>8</sup> This methodology avoids the timing problems which can result from the linkage of air and ground battle models [Ref. 5].

command and control installations, and long range attacks on troop concentrations. This is accomplished by assuming a specified amount of destruction or disruption is inflicted for every ton of ammunition fired by "headquarters artillery". These units represent those which provide indirect fire support to the battle but are not subject to the battle attrition. Attrition effects, as in the case of those caused by air attacks, are subtracted from initial force levels used in the subsequent Lanchester ground attrition calculations. Disruption of command and control is accomplished by increasing factors which result in lengthening a unit's "delay for orders" activity event and thus slowing the pace of the battle.

As a consequence of this methodology, the real combat systems represented by "Headquarters artillery"<sup>9</sup> do not enter into any attrition calculations. This is a result of the square law simplification which leaves no possibility of explicitly partitioning indirect fires between attacks on enemy headquarters, fire support means, or maneuver forces. Because of this methodology, the sets of inputs listed in Appendix B which refer to "Headquarters artillery" are set to zero, thus removing this class of inputs from the model.

---

<sup>9</sup> Romero suggests multiple rocket launcher systems can be described in this way. [Ref. 1, sec A-1.7]

## E. SIMULTANEITY

MOSCOW is essentially a system of simultaneous equations which, when solved iteratively, converge to a solution. The need for iterative calculations stems inherently from the model's structure in three ways<sup>10</sup>. First, combat is initiated when enough combat power on each side is massed to achieve an engagement threshold determined by the force ratio requirements of both Red and Blue. The time needed to mass this combat power is assumed to be inversely proportional to the density of the respective forces. Since the density of the Blue force is a function of the model's output, the model is self referential. Additionally, since an increase in the number of Blue units results in a proportional increase in force density, which in turn decreases the time required to mass sufficient Blue forces, the result is a subsequent decrease in the number of Blue units required. Thus, the system converges. The same type of relationship holds for combat activities which delay attacking units.

Combat events, such as air attacks directed against an attacking force, typically delay an attacker's advance. The amount of delay imposed on an attacker in a given time period tends to decrease as the defending force is attrited. But any event which serves to increase the duration of the battle will, necessarily, allow more time for the defender to be

---

<sup>10</sup> See Romero sections 4.3.1 and 4.3.4

attrited, resulting in a decrease of the battle's duration. Thus, this system must converge to a point which balances the overall battle duration and force levels.

Lastly, MOSCOW's definition of tactical mobility establishes the "average" engagement distance which scales the lethality coefficients used to compute attrition. As the duration of an engagement increases, the closure of forces results in a decrease in the average engagement distance with the result that lethality is increased. Hence, the length of the battle decreases. This system must also converge as in the previous cases.

The important consequence of simultaneity is that model output is made more accurate by increasing the number of recalculations performed on a given set of inputs. The number of recalculations for any given level of accuracy must be established by experiment<sup>11</sup>.

---

<sup>11</sup> Romero suggest 12 - 15 iterations are sufficient.

### III. ASSESSMENT OF METHODOLOGICAL LIMITATIONS

MOSCOW's methodology limits its suitability to accurately represent certain combat scenarios.

#### A. ANNIHILATION OF FORCES CANNOT BE APPROACHED

Stochastic models which attempt to account for randomness in combat are known to produce results which differ from otherwise equivalent deterministic modeling formulations<sup>12</sup>. These differences appear in square law attrition processes when two side have approximate parity (equality terms of numbers and lethality) or when one side approaches a point of annihilation. In the first case, parity of forces will result in MOSCOW's underestimating the length of a battle [Ref. 2]. Although this parity is unlikely in attack scenarios (logically, rational doctrine precludes attack with little hope of victory), it is possible, perhaps common, in the defense<sup>13</sup>. In MOSCOW, however, any discrepancy between deterministic and stochastic results should be minimized because actual battle attrition occurs in only a small

---

<sup>12</sup> See Hartman, sec F.6

<sup>13</sup> Historical examples from World War I suffice to make this point.

fraction of the total campaign length.<sup>14</sup> Thus, this case is of little concern.

In the second case, where one side is annihilated, Hartman [Ref 2, sec F-6] demonstrates that a deterministic square law model will overestimate the winning force size while underestimating the size of the losing force. Furthermore, an annihilation condition would violate an assumption of constant "area fire" target availability<sup>15</sup>. Because this limitation is fundamental to it's underlying formulation, MOSCOW should not be used in such circumstances. The point where annihilation effects become serious, however, is unknown. This is an area for further research.

#### B. MINIMAL LINKAGE OF AIR-GROUND BATTLE

Because attrition of ground forces produced by air attacks is only a function of the total number of sorties, MOSCOW cannot directly account for any synergism between air and ground forces. Within a given number of sorties, only questions concerning allocation between close air support and air interdiction missions can be addressed. If the question to be answered involves trying to determine the "best"

---

<sup>14</sup> See Romero, Appendix B, Sec 2. Romero observes that, historically, units spend proportionally little time engaged in actual combat.

<sup>15</sup> See Appendix B.

allocation, MOSCOW is ill suited to provide answers since it has no mechanism for optimization<sup>16</sup>.

#### C. CONSTANT PROPORTION OF DIRECT AND INDIRECT FIRE SYSTEMS

As shown in Appendix C, the reduction of a complex attrition processes between direct and indirect fire systems requires the simplifying assumption that such attrition leaves the proportion of direct and indirect fire systems constant throughout the battle. The limitation this assumption places on the use of MOSCOW is unknown. The possibility exists, however, that a battle process which results in wide variation of this proportion will not be accurately modeled in some instances. This is another topic for further investigation.

---

<sup>16</sup> See Romero Sec IV.

#### IV. ANALYSIS FOR ASSESSING MODEL PERFORMANCE

In order to assess the performance of the current version of MOSCOW, the sensitivities exhibited by the model to changes in various inputs were calculated from the results of factorial experiments. These results were examined using two criteria: the magnitude of change the variation of an input produces in specific measures of effectiveness, and whether or not the direction of the resulting change agrees with intuition. Although the interpretation of these results does not represent a formal verification of MOSCOW, it does illuminate which portions of the model seem to perform according to expectation and which areas may contain obvious errors.

##### A. FUNDAMENTAL ASSUMPTIONS

This analysis relies on an assumption that a suitable low resolution land combat model will exhibit one basic characteristic. This characteristic is that, all other things being equal<sup>17</sup>, a small change in one force attribute or scenario circumstance will produce a correspondingly small change in the amount of force attrition which results from combat. This assumption is reasonable in that it agrees with

---

<sup>17</sup> This is essentially the situation in MOSCOW, where the process of input estimation effectively fixes the tactics and organizations of the combatants.

intuition. Suppose, for example, that the lethality of direct fire weapons increases by a small increment because of a technological improvement. With no change in tactics, a tremendous increase in combat capability would be unexpected. It would be far more likely to observe some incremental improvement in combat effectiveness, making the opposing force a "little" easier to kill. A similar argument can be made for an incremental decrease of a force attribute. As applied to MOSCOW, this reasoning suggests that small changes in input variables should produce correspondingly small changes in the number of Blue forces needed to attain a specified attrition of Red.

This reasoning implies a general measure of MOSCOW's overall suitability is to assess its sensitivity to small changes in inputs. This approach requires quantitative definitions be assigned to the terms "sensitivity" and "small changes". To this end, a small input change is defined<sup>18</sup> as one which does not alter the level of the input by more than 10%. Similarly, a model output measure of effectiveness is considered "sensitive" with respect to a specific input variable if changing the level of the input by a given proportion produces a change in output of equal or greater

---

<sup>18</sup> This definition is not purely ad hoc. It is consistent with current U.S. Army readiness classifications which consider a unit "fully mission capable" if it possesses 90% or more of its authorized strength in personnel and equipment.

proportion. For example, if a 10% change in an input results in a 10% or greater change of an output, the output measure is "sensitive" to the input variable at the 10% level.

A further possibility is that the effects of varying two or more inputs may interact in combination to change the levels of output measures of effectiveness. If inputs are varied in the same proportion, a reasonable definition of sensitivity is to call an output "sensitive" to the interaction of inputs if the magnitude of the resulting change is equal to or greater than the proportional changes in the inputs which produced the interaction<sup>19</sup>. Thus, if two inputs are varied by 10% and the resulting interactions produce a change in output which is equal to or greater than 10%, the output is considered "sensitive" to the interaction of these inputs at the 10% level.

## B. FACTORIAL EXPERIMENT DESIGN

One well known technique which examines the effects of varying two or more inputs is to use experiments with a factorial design. These methods are well understood and easily applied to experiments with MOSCOW because, as a completely deterministic model, questions concerning the experimental significance of effects are irrelevant due to the fact that multiple model runs using identical inputs will

---

<sup>19</sup> This definition agrees with the way levels of interaction are computed in factorial experiments. See Davies, section 7.33.

produce identical results. Thus, the natural variation of experimental results, common to "real world" or stochastic processes, never occurs and analysis of variance cannot be performed. The use of a factorial design with this simplification reduces to a procedure for calculating the main effects of input variables and their associated interactions.

Of all possible designs for factorial experiments, the simplest way to compute both main effects and interactions of inputs is using a  $2^n$  factorial design [Ref. 6:pp. 257]. This method examines the effects of varying  $n$  inputs. Each input takes one of two values: a lower, or base level, and a higher level. By examining the effects of all possible combinations of input levels, the main effect of each input can be calculated by finding the difference between the average model output when an input is held at a high level and the average observed at lower input levels. For two different inputs, A and B, the interactions between A and B can be measured by computing the difference in the effect of A when B is at a higher level, and the effect of A when B is at a lower level<sup>20</sup>. Details of this method are in Appendix F.

#### C. ADVANTAGES AND LIMITATIONS OF $2^n$ FACTORIAL DESIGN

As shown by Davies [Ref. 6, sec 7.27], the principle advantage of a factorial design is maximum efficiency when compared to other methods. Complete factorial experiments

---

<sup>20</sup> See Davies, Section 7-44, p. 259-260

such as a  $2^n$  design are free from the confounding of interactions found in partial designs. The fundamental limitation imposed by a  $2^n$  design is that it involves performing a number of experiments which rises exponentially with the number of variables. Additionally, the algorithm used to compute main effects and interactions has complexity  $O(2^n)$ . In a practical sense, this complexity means that computation time and computer memory requirements increase by a factor of  $2^n$  as the number of inputs increase. This fact limits the number of variables which can be considered in such an experiment using the model's current LOTUS format and a Z-248 computer to about ten input variables<sup>21</sup>.

#### D. GROUPING OF INPUTS FOR EXPERIMENTATION

The two sets of inputs found in Appendix B represent two completely different scenarios which use different scales of resolution. The Attack scenario is fought with Brigade/Regiment sized units (approx 300 vehicles per unit) while the Defense scenario is an engagement between Divisions (approximately 1000 vehicle per unit). To see if the sensitivity of MOSCOW's inputs appears to be relatively consistent across these two scenarios and two scales, 12 factorial experiments were performed on each scenario using corresponding inputs. To meet the limitation of no more than

---

<sup>21</sup> Using MOSCOW's LOTUS programming format, a  $2^{10}$  experiment requires approximately 18 hours of computing time with a Zenith 248 series personal computer.

ten input variables per experiment, input groups were chosen in an ad hoc attempt to find large interactions. For each scenario, experiments were generally partitioned between Red and Blue with separate experiments on groups of logically related input variables such as weapon attributes, logistic/maintenance constraints, battle scaling inputs, unit description, and inputs related to activity cycle construction. Additionally, one experiment dealt with what appear to be critical scenario variables such as the length of time each day usable for combat and the number of Red units allowed to survive. This last input defines the Blue force success criteria. A complete listing of input variables used in each experiment is in Appendix G.

#### E. SELECTION OF MODEL OUTPUTS USED IN VARIABLE COMPARISON

The question of which model outputs are the "best" to use as a means of evaluating the effects of changes in model inputs is difficult because existing documentation is silent on this issue. For the lack of a better method, it seems reasonable to use outputs which most directly result from MOSCOW's underlying attrition and activity cycle algorithms because the inherent sensitivity of these algorithms is the issue which bears on the model's overall suitability. Outputs which are a direct measure of Blue's force requirements clearly meet this criteria. In MOSCOW, this total force requirement number is expressed as the sum of two values: the

number of Blue units required at the start of combat, and the number of Blue units required as reinforcements<sup>22</sup>. Since these two outputs are obviously basic to the model's purpose, their selection is a logical choice. Two other outputs from MOSCOW's supplementary calculations also meet this criteria since they are a direct measure of activity cycle calculations. These outputs measure the number of Attack and Defend cycles Blue forces are able to successfully execute during a battle. Lastly, one of MOSCOW's supplementary outputs gives the ratio of Red to Blue forces required to meet Blue victory conditions. Since such ratios are a commonly used measure of force effectiveness, this output was selected because of its familiarity<sup>23</sup>.

Each of these five outputs are direct results of attrition and activity cycle calculations. Other outputs, notably those dealing with personnel, fuel, and ammunition requirements, are

---

<sup>22</sup> Romero refers to initial Blue force requirements as "standing" Blue units while follow on forces are called "replacements"

<sup>23</sup> This familiarity is expressed in two ways. First, force ratio attrition models use the ratio of fire power indices as a measure of the relative combat power in a battle (see Hartman, Chapter 4). Although MOSCOW does not use this technique, such a ratio measure is part of folklore from earlier ATLAS and IDAGAM models. The concern with force ratio in terms of numbers of weapons is also a common measure used by Soldiers to assess the relative strength of forces in a battle. This is the interpretation used in MOSCOW.

not computed by attrition calculations<sup>24</sup>. As such, none of these outputs were used in sensitivity experiments. However, as more information about MOSCOW's algorithms becomes available, some of these outputs may prove to be better measures of input sensitivity than those chosen for this investigation.

#### F. MODEL ITERATION REQUIREMENTS

A consequence of the simultaneity inherent to MOSCOW is that successive spreadsheet recalculations (model iterations) produce a convergence of model outputs to unique values which are a function of the inputs. The practical problem the user faces is to determine how many recalculations are sufficient to produce "adequate" convergence. By adequate is meant the convergence necessary to produce results with a level of accuracy specified by the model user.

For the investigation of input sensitivity, the minimum number of recalculations sufficient for convergence were found experimentally for both Attack and Defend scenarios. Adequate convergence was defined as the number of recalculations beyond which any additional recalculation will change the number of "Standing" Blue units required by less than half of one Blue combat vehicle. This definition of adequate convergence is sufficient to insure model resolution to the level of an

---

<sup>24</sup> The model developer, Phil Romero, confirmed this interpretation of the secondary nature of logistic requirements calculations during discussions on 15 April 1988.

individual Blue combat vehicle. While this resolution may be excessive, especially for battles involving hundreds of combat vehicles, it is the highest level of resolution which makes any practical sense<sup>25</sup>. Appendix H contains a description of the experimental procedure used to find the iteration requirements for both scenarios. The results of these experiments suggest that 21 recalculations will produce adequate convergence in the Attack scenario while the Defense scenario needs only 15 recalculations.

#### G. IMPLEMENTATION OF A $2^n$ FACTORIAL EXPERIMENT WITHIN MOSCOW

Programming factorial experiments within MOSCOW's LOTUS spreadsheet format was done using LOTUS macro commands. The code implementing a  $2^n$  experiment was imbedded in a sufficiently large range of empty cells. This program addition contains three main sections. The first section computes the difference between an experimental variable's upper and lower levels. The second section consists of a series of nested loops which insure the levels of desired inputs are varied to produce all input level combinations specified by the factorial design. This section also writes a table of results which records the level of each experimental variable and the corresponding value of the five outputs for each experimental trial. The last section writes

---

<sup>25</sup> Since the size of a Blue unit is naturally expressed as a whole numbers of combat vehicles, resolution in model outputs beyond one vehicle makes no sense.

the results table to an output file for later analysis.

Details of this macro coding are in Appendix I.

The computation of main effects and interactions was done by first converting the tabular results produced by factorial experiment macros from LOTUS spreadsheet format to one which could be read directly by an APL\*PLUS interpreter. This was accomplished using the file conversion facilities within the STATGRAPHICS statistical software package. Main effects and interactions were computed using an interactive APL function which implements the algorithm in Appendix F. A listing of this function is in Appendix J.

## V. RESULTS OF SENSITIVITY EXPERIMENTS

### A. MAGNITUDE OF MODEL INPUT SENSITIVITY

The interpretation of the magnitude of both main effects and interactions relies on the observation that if interaction terms are "large", then the corresponding main effects of the inputs which produce the interaction do not have much meaning [Ref. 6, sec 7.34]. This is a practical result of the observation that if a combination of inputs is responsible for a large effect, then the degree to which a change of one input produces a change of model output must depend heavily on the levels of other inputs. Conversely, if interactions are small, then the effects produced by different inputs must be essentially independent. This relationship yields a procedure for analyzing the results of a factorial experiment which is to compare the magnitude of interactions with the corresponding main effects, determining whether or not the effects of the inputs are independent. Having found the independent main effects and dominating interactions, the inputs which produce these results can then be examined on the basis of intuition about expected model performance.

Table 3 contains the significant interactions found for all factorial experiments; that is, the interactions where a 10% change in inputs produces a 10% or greater change in model output. The resulting changes of model output are in terms

TABLE 3

## Significant Input Interactions

of the standing Blue units (STAND) and replacement Blue units required (REPL). These values express the numbers of Blue brigades in the Attack scenario and Blue divisions in the Defense scenario required to meet victory conditions. The output which reports the change in the ratio of the overall number of forces (R:B) has no units, while the change in the number of Blue attack (ATK) and defense (DEF) activity cycles corresponds to operations at the brigade level in the Attack scenario and division level in the Defense scenario. Of the approximately 10,000 interactions examined in 24 factorial experiments, only six inputs combine to produce large interactions.

Comparing these interactions with the corresponding table of large main effects in Table 4, it is immediately apparent that interactions involving the input representing the amount of command and control errors induced on Red forces by Blue electronic warfare (EW) efforts has no effect on any significantly large interactions. Large pairwise interactions with this input equal the main effect of the paired input. For example, the interaction of the inputs Desired Red Attacking Force Ratio and Red  $C^3$  Error by Blue Electronic Warfare produces a R:B (force ratio) interaction of  $-.565$  in the defense scenario. This is exactly equal to the main effect of the Desired Red Attacking Force Ratio on the R:B output MOE. Thus, with the exception of the interaction of

Desired Red Attacking Force Ration and Red %Firers Direct Fire, all significant interactions in the Defense scenario reduce to main effects. The one remaining interacting is only barely significant in the output MOE R:B.

The interaction of the inputs which represent the number of Blue and Red engineer units in the attack scenario follows the same pattern. Comparing this interaction with the corresponding main effects reveals that the combined effect of these inputs appears to depend only on the level of Red engineer units with the unexpected result that the change produced by the interaction of Red and Blue engineers is exactly equal to the negative of the main effect for the number of Red engineers<sup>26</sup>. This result is completely unexpected since the obvious relationship is that Red engineer units tend to negate the efforts of Blue engineers and visa versa. Thus the expected result is surly that the interaction of these two inputs should be small in relation tho the corresponding main effects. This result indicates a possible problem with the part of MOSCOW's algorithm which accounts for the influence of engineer assets on the attrition process. This indication is reinforced by the observation, from Table 4, that the four inputs which specify both the number of engineer units and their capabilities relative to each other produce significant main effects.

---

<sup>26</sup> In fact, with the exception of negation, the results are identical for all model outputs to four decimal places.

Another area of difficulty is MOSCOW's sensitivity to changes in the number of Red command and control errors produced by Blue electronic warfare. Not only does the Defense scenario exhibit extreme sensitivity to this input, but the observed relationship between an increase in Red command and control errors appears to result in increased Blue force requirements. This clearly violates the intuition that those factors which are a detriment to Red's combat capability should be of benefit to Blue. Additionally, if the observed results are correct, then the reported increase in Blue standing and replacement unit requirements should translate into an increase in the total numbers of Blue forces and, therefore, a reduction in the force ratio (R:B). But this is contrary to the observation which shows a large increase in force ratio. Since no obvious errors can be found in either the programming of the factorial experiment or in data analysis, the possibility of an inconsistency involving this input within MOSCOW clearly exist.

Lastly, although MOSCOW may appear sensitive to the number of vehicles found in both Red and Blue units, this is not the case. A simple example which makes this point clear is to consider the Attack scenario. Blue units in this scenario consist of 369 vehicles and MOSCOW computes a standing force requirement of 11.37 Blue units. This translates to an initial need for 4196 Blue combat vehicles. If the size of a Blue unit is increased by 10%, to 406 vehicles, the main

effect of this change, as reported in Table 3, will be a decrease in the number of standing Blue units required by 1.56 units. The total number of Blue vehicles required with larger Blue units is:

$$(406 \text{ veh/unit}) \times (11.37 \text{ units} - 1.56 \text{ units}) = 3983 \text{ veh}$$

This represents a decreased requirement for Blue combat vehicles of only 5%. Thus a 10% increase in the size of blue units results in only a 5% reduction in the total number of Blue combat systems, demonstrating that this change of model input meets the criteria of producing a small change in output. Similar results hold for changes in the number of vehicles assigned to Red units. The remaining inputs which produce significant main effects for at least one output do appear to have obvious explanations. The appropriateness of model sensitivity to changes in these inputs is a subject for further study.

#### B. GENERAL ANALYSIS OF MAIN EFFECTS

Experience holds much information about how the relative capabilities of combat forces will change under the pressure of improving technology. Historically, this pressure has developed continuous improvements in weapon systems. Most often, these improvements are seen as increases in weapons performance: more accurate guns of greater lethality, capable

of firing at longer ranges, better armor to meet the threat of better weapons, greater mobility under conditions of adverse terrain and weather, more responsive logistical support, and a general improvement in command, control, and communications capabilities. In every case "better" weapon systems are seen to translate into "more capable" forces.

The clear assumption underlying this reasoning is that an incremental technological improvement of a weapon results in an incremental increase of a combat unit's overall capability. Because this idea has great historical appeal and many of MOSCOW's inputs are the direct expression of weapon system characteristics, a reasonable expectation of model performance is that the main effect of a small improvement in Red weapons capabilities will require an increase in the number of Blue units if the definition of victory remains constant. The converse should be true if Blue has the benefit of improved technology. In terms of the expected changes in model outputs examined as the result of factorial experiments, the increase of a Red force attribute should logically produce an increase in the number of standing and replacement Blue units, a decrease in the numerical ratio of total forces (R:B), and an increase in the numbers of the Attack and Defend cycles which Blue must accomplish to achieve victory. The opposite changes should occur if Blue receives the benefit of improved technology. Similar reasoning can also be applied to explain the changes in output that should logically be expected from

changes in victory conditions such as the depth of Red penetration when Blue is defending or the amount of attrition to be inflicted on Red by Blue attacks.

The expectations about the influence a small change in input will have on model output can be compared to the input's observed main effects as computed from the results of a factorial experiment. If the directions of the observed changes agree with intuition, there is no reason to reject the notion that the model appears to be performing according to expectation. If, on the other hand, changes in input produce unexpected changes in output, then two possibilities exist. First, the input's main effect may be dominated by interactions with other inputs. This is the situation discussed earlier where the existence of large interactions indicates strong dependency between interacting inputs with the result that little importance can be associated with the computed main effect. The second case is that, if the main effect dominates, the model produces results which are contrary to expectation.

The only requirement for making use of this method is that some rule must be used to decide how large a given interaction must be before the associated main effects become unimportant. For the purpose of this analysis, main effects are considered inconsequential if a interaction term exists which has a magnitude which is equal to or greater than one half the magnitude of the main effect. The relative importance of any

main effect can be decided by comparing the magnitude of the main effect to the magnitude of the magnitude of the input's largest interaction term. With this criterion, the main effects computed from the results of factorial experiments can be examined to discover those areas where model performance may not agree with intuition. Table 5 contains the main effects computed for the same Blue force inputs in both the Attack and Defend scenarios. A reasonable expectation of the effects of a small increase of the first input (# Blue Vehicles / Blue Unit) is that such units will be slightly more capable, hence the number of units needed as standing and replacement forces should decrease along with the number of attack and defend cycles, while the numerical ratio of forces (R:B) should increase. This expected result is identical with observation. Furthermore, all main effects can be shown to dominate their corresponding interactions.

The last four inputs of Table 5 represent cases where the expected influence of small increases is a reduction in Blue unit capability. Thus, the requirements for standing and replacement units along with the numbers of attack and defend cycles should increase, whereas the numerical ratio of forces should decrease. Comparing this expected result with the observation reveals numerous discrepancies. In Table 5, for example, the main effects observed for the last input appear to completely contradict expectation. However, in each case where an unexpected result occurs, the observed main effect

can be shown to be dominated by interactions. The general result of applying this method to many inputs suggests there is no evidence to reject the hypothesis that MOSCOW produces results which meet with expectations. A complete listing of all main effects as calculated from the results of all factorial experiments is in Appendix K.

The remaining two inputs, Desired Blue Attacking Force Ratio and Percentage of Blue Firers Using Direct Fire are examples of inputs which do not lend themselves to this type of analysis since no clear intuition exist about the behavior of these inputs. However, all the main effects for the first of these inputs are dominate and consistent with the hypothesis that an increase in attacking force ratio is not

favorable for Blue. For the last input, all main effects except for the R:B force ratio in the Attack scenario are dominate. This suggest that increasing the numbers of direct fire weapons is favorable for Blue. If the objective of analysis was to explore whether or not MOSCOW was producing results which are consistent with other models, these types of comparisons may be of value.

## VI. CONCLUSIONS AND RECOMMENDATIONS

### A. CONCLUSIONS

As seen in the previous section, this analysis has identified only two areas where obvious problems appear to exist within MOSCOW's algorithms. The first problem involves the unexpected model sensitivity to changes in engineer attributes. The second problem is the unexplained sensitivity to the amount of command and control errors induced by enemy electronic warfare. Where intuition exists, changes in other inputs appear to influence the model in a manner that agrees with expectations.

With the above deficiencies corrected, there is no evidence showing that MOSCOW could not be calibrated to agree with the results of a higher resolution model, such as Vector-In-Commander. MOSCOW could then explore scenarios which result from small percentage changes of inputs. This would be the case as long as the proportion of direct and indirect fire weapons remains relatively constant.

### B. RECOMMENDATIONS

The assumption that the proportions of direct and indirect fire combatants will remain constant for the duration of combat represents MOSCOW's fundamentally limiting assumption. The exact scope of this limitation, stemming from the model's underlying square law formulation, is unknown. Future research should evaluate this limitation in comparison with

other formulations, such as that proposed by Helmbold [Ref. 3]. This investigation may discover an attrition methodology which proves better able to handle a wider variety of situations, yet does not increase the model's complexity or number of inputs by a significant amount. Pursuing the answers to these questions will determine which method is the "best" to use as a basis for the attrition calculations within MOSCOW.

## APPENDIX A. LIST OF ABBREVIATIONS USED IN MOSCOW

Currently, MOSCOW's output screens are restricted to a width of 80 columns. A consequence of this restriction and the large amount of information contained in MOSCOW's output is that many nonstandard abbreviations are used to make output readable. The following is a list of common abbreviations used in MOSCOW.

AMMO	Ammunition
AMT REQD	Amount Required
ATK	Attack
AVG	Average
AVE/DAY	Average per Day
BLUE	Blue units -- Friendly Units
CUM	Cumulative
DEF	Defense
ENG	Engineer Unit
ENGMENT	Engagement
HQS	Headquarter(s)
LIFT	Supply Transport Capability
MIN	Minimum
MVR	Maneuver Unit -- Combat Unit
MVR-EQ/D	Maneuver Unit Equivalent per Day
MVR+EQVS	Standing Forces plus Replacements
MVRS	Maneuver Units -- Combat Units
OTHER	Other supplies requirement (food, water, etc.)
PEAK/DAY/MVR	Maximum rate of Personnel Casualties per Day per Maneuver Unit
PERS/DAY	Personnel per Day
POL	Petroleum and Lubricants

RED  
REPL

Red Units -- Enemy Forces  
Replacements (Soldiers who  
take the place of casualties)

#S VEH  
# HQs

Number of Supply Vehicles  
Number of Headquarters Elements  
Required for Combat Operations

## APPENDIX B. DESCRIPTION OF MODEL INPUTS

The inputs used in describing land combats scenarios in MOSCOW belong to one of six general categories. This grouping is described in section 4.3.5, A New Approach for the Design and Evaluation of Land Defense Concepts, RAND Corp report R-3643-A, Philip J. Romero.

### A. TERRAIN

MOSCOW requires that the user provide some process which quantifies the trafficability, defense strength, and target availability within the zone. These values are then averaged across the zone to represent a uniform characterization of a scenario's terrain.

### B. LIMITS FOR BLUE

These inputs represent the resource constraints for the Blue (friendly) force expressed in terms of total maneuver units available, personnel casualties sustainable, replacements of personnel and equipment available (total and daily rate), and supplies. These values are only used for comparisons against resource requirements.

### C. RED THREAT AND ZONE GEOGRAPHY

These inputs describe the size of the Red (enemy) force and the rectangular dimensions of the geographic zone the campaign is fought. This geographic description also includes

the average dimensions and number of choke points which limit Red operations and the number of engineer units which support Red's tactical/operational plan.

#### D. SUCCESS CRITERIA AND OPERATIONAL-LEVEL POLICY FOR BLUE

These inputs define the Blue force tactical objective which is the number of Red units which will be allowed to survive. Additional inputs define the deployment of Blue forces in the zone of operations, the amount of supporting engineer units, aggressiveness, and linearity of combat operations.

#### E. LIMITS FOR BLUE

These inputs specify an upper bound on the resources which Blue can use during the battle. They do not enter into MOSCOW's attrition calculation, but are used to compare model outputs with user defined maximum resource limit. As such, these inputs are set to arbitrary levels.

#### F. MANEUVER UNIT DESCRIPTION

This class of input broadly defines the combat characteristics of Red and Blue forces. As such, it contains specifications which describe both unit capabilities and aggregate vehicle characteristics.

#### G. SUPPORTING AIR, ARTILLERY, AND ENGINEER CAPABILITIES

These define the quantity of air support available to both sides. This definition includes the quantity of aircraft

(fixed wing and helo) which supports each side, how these assets are allocated between close air support and air interdiction missions, their lethality, and a rough measure of the attrition effects of air defenses. Supporting engineer assets are described by scaling coefficients which quantify Blue engineers' ability to delay Red and Red engineers' ability to enhance Red mobility. Artillery inputs are not useful and are omitted from these input sets.

#### H. LISTING OF SPECIFIC INPUTS

This paper uses the unclassified inputs developed by TRAC-FLVN as a starting point for experimental investigation into the sensitivity of MOSCOW to selected inputs. The methodology used to generate these inputs and specific details of the scenarios represented are in draft technical report, A Methodology for Estimation MOSCOW Inputs, James C. Hoffman, 1988. Broadly speaking, these inputs attempt to demonstrate a method of generating suitable model inputs which represent the attack, using airland battle doctrine, of a U.S. Corps to destroy the lead echelon of an opposing Combined Arms Army employing Soviet type equipment. The same methodology is also used to produce inputs representing the defense of this Corps against a Combined Arms Army's deliberate attack. Both scenarios occur on the same type of terrain in NORTHAG.

## APPENDIX C. DERIVATION OF MODEL METHODOLOGY

Fundamental modeling assumptions for MOSCOW provide a way to reduce a complicated system of differential equations to a simple Lanchester "square law" form.

Assume the following system of equations which describes the attrition interactions between two combatants, both using direct and indirect fire weapons.

$$dX_D/dT = -(a_1 Y_D + b_1 Y_I X_D) \quad (1)$$

$$dX_I/dT = -(a_2 Y_D + b_2 Y_I X_I) \quad (2)$$

$$dY_D/dT = -(a_3 X_D + b_3 X_I Y_D) \quad (3)$$

$$dY_I/dT = -(a_4 X_D + b_4 X_I Y_I) \quad (4)$$

$X_D$  and  $Y_D$  refer to the respective numbers of direct fire weapons on each side while  $X_I$  and  $Y_I$  correspond to indirect fire systems. The  $a_i$  are the usual "square law" attrition coefficients; the  $b_i$  are attrition coefficients given in the "linear law" case. The dimensionality of these coefficients is:

$$a \text{ units} = \text{S-killed} / (\text{R-firer})(\text{unit time})$$

$$b \text{ units} = \text{S-killed} / (\text{S-target})(\text{R-firer})(\text{unit time})$$

Clearly, this formulation accounts for typical tank vs tank, artillery vs tank, tank vs artillery, and artillery vs

artillery engagements. MOSCOW reduces this complicated system of equations to the traditional "square law" case by assuming the rate at which targets become available to indirect fire is constant for the duration of battle. This assumption implies that artillery can only "see" a constant number of targets independent of the actual size of the opposing force. This assumption also implies that neither side approaches annihilation. By defining the following constant terms, equations 1 - 4 can be reduced to a traditional square law formulation as follows:

Define constants:

$$c_1 \ll X_0(t)$$

$$c_2 \ll X_1(t)$$

$$c_3 \ll Y_0(t)$$

$$c_4 \ll Y_1(t)$$

Then, by substitution,

$$dX_0/dT = -(a_1 Y_0 + b_1 c_1 Y_1) \quad (5)$$

$$dX_1/dT = -(a_2 Y_0 + b_2 c_2 Y_1) \quad (6)$$

$$dY_0/dT = -(a_3 X_0 + b_3 c_3 X_1) \quad (7)$$

$$dY_1/dT = -(a_4 X_0 + b_4 c_4 X_1) \quad (8)$$

Summing pairs of equations 5,6 and 7,8:

$$d(X_0+X_1)/dT = -(a_1 + a_2)Y_0 - (b_1 c_1 + b_2 c_2)Y_1 \quad (9)$$

$$d(Y_0+Y_1)/dT = -(a_3 + a_4)X_0 - (b_3 c_3 + b_4 c_4)X_1 \quad (10)$$

By assuming the proportion of direct and indirect fire systems as a fraction of the total force remains constant, then:

$$X(t) = X_0(t) + X_1(t)$$

$$Y(t) = Y_0(t) + Y_1(t)$$

Then define such constants  $d_1, d_2, d_3, d_4$  so that:

$$X_0 = d_1 X \quad \text{and} \quad X_1 = d_2 X$$

$$Y_0 = d_3 Y \quad \text{and} \quad Y_1 = d_4 Y$$

Substituting into equations 9 and 10 and collecting terms gives:

$$dX/dT = -[(a_1 + a_2)d_3 + (b_1 c_1 + b_2 c_2)d_4]Y \quad (11)$$

$$dY/dT = -[(a_3 + a_4)d_1 + (b_3 c_3 + b_4 c_4)d_2]X \quad (12)$$

These equations are equivalent to the square law case.

#### APPENDIX D. ATTRITION CALCULATION EQUATIONS

As derived by Hartman [Ref 2, chapter 7, sec 5], the following equations result from the Lanchesterian square law formulation of attrition and explicitly determine the duration of such a battle where:

$X_0$  and  $Y_0$  are initial force levels

$a$  = coefficient of  $Y$  force attrition

$b$  = coefficient of  $X$  force attrition

$X_{bp}$  = "Break point" for  $X$  force

$t_{xpb}$  = time required to reach  $X_{bp}$

$s = 1/2$ , exponential parameter

The "break point" is the point, in terms of force size, that a combatant will chose to disengage from combat so as not to sustain further losses. A symmetric pair of equations exist to express these relationships for the  $Y$  force.<sup>27</sup>

$$X_{bp} = \frac{1}{2} \left\{ \left[ X_0 - (a/b)^s Y_0 \right] e^{(a/b)^s t_{xpb}} + \left[ X_0 - (a/b)^s Y_0 \right] e^{-(ab)^s t_{xpb}} \right\}$$

---

<sup>27</sup> The expressions for the  $Y$  force can be obtained by switching the definitions of variables, substituting  $Y$  for  $X$ ,  $a$  for  $b$ , and visa versa.

$$t_{x_{bp}} = (ab)^{-s} \ln \left\{ \frac{X_{bp} - \left[ X_{bp}^2 - X_o^2 + (a/b)Y_o^2 \right]^{-s}}{X_o - \left[ (a/b)Y_o \right]^s} \right\}$$

Taken together, these equations represent the mechanism MOSCOW uses to compute either the time required for combat or the amount of attrition which results from combat. As solutions of a differential system of equations with specified initial conditions, the evaluation of these equations must result in unique solutions. Hence, transformations which are not identity relations cannot represent solutions of the original differential system. Since an change of the exponential parameter,  $s$ , to any value other than  $1/2$  is not an identity transformation, the result of such changes will be to fundamentally change the nature of MOSCOW's attrition relationship. This means that the possibility of changing the exponential parameter to values other than  $1/2$ , as proposed by Romero [Ref. 1, figure C-15], will result in an attrition relationship which is different from the "square law" formulation.

## APPENDIX E. AIR-GROUND ATTRITION EQUATIONS

Current descriptions of MOSCOW's algorithms do not elaborate on the algorithm used to compute the total number of aircraft sorties flown in any given campaign. Clues, however, exist in the code of the model and the inputs required for its computations. Apparently, this algorithm assumes a constant rate of attrition which decreases the number of aircraft which are available over time using the relation:

$$S_i = (1-P)^u X_0$$

where  $S_i$  = # of sorties available in period  $u$   
 $P$  = rate of aircraft attrition  
 $X_0$  = initial number of aircraft available

The sortie period is a time index defined by the relation:

$$u = aT_b$$

where  $a$  = sortie rate measured in sorties/day  
 $T_b$  = length of the battle in days

By treating this as a continuous process, the total number of sorties available in a battle of length (t) and sortie rate (a) is simply:

$$S = \int_0^u (1-P)^r X_0 dr$$

$$S = [X_0/\ln(1-P)] [(1-P)^u - 1]$$

since  $u = aT_b$

then,

$$S = [X_0/\ln(1-P)] [(1-P)^{aT_b} - 1]$$

## APPENDIX F. FACTORIAL EXPERIMENT RESPONSE CALCULATION

The following method to calculate the effects produced by changing the levels of variables in a  $2^n$  factorial experiment is an adaptation of a tabular approach attributed to F. Yates<sup>28</sup>. Using this method to compute the main effect of a single variable reduces to calculating the difference between the average output of all trials where the variable is at a high level and the average output when the variable is at a low level. To accomplish this, suppose a level coding vector  $X_i$ , containing  $2^n$  elements, is used to record the levels of the variable  $X_i$  in all trials of an experiment. Within this vector, the  $k^{\text{th}}$  element contains 1 or -1. A "1" corresponds to trials with the variable at a high level; "-1" corresponds to trials at a low level. If the results of all trials for a single model output,  $Q_j$  are collected in a vector  $Q_j$ , then these two vectors,  $X_i$  and  $Q_j$ , can be used to compute the main effect of a variable by evaluating the expression:

$$\text{Main Effect } X_i = \frac{\sum_{k=1}^{2^n} X_{ik} Q_{jk}}{2^{n-1}}$$

---

<sup>28</sup> See Davies, Section 7.45, p. 263

The interaction between two variables is defined as half of the difference between the average output when the variables are at similar levels and the average when they are at dissimilar levels. As demonstrated in Davies<sup>29</sup>, the previous method of recording the levels of variables in any trial can be used to compute these interactions by observing that, for two variables with corresponding vectors  $X_1$  and  $X_2$ , the two-way interaction is:

$$X_1 X_2 \text{ Interaction} = \frac{\sum_{k=1}^{2^n} (X_{1k} X_{2k}) Q_{jk}}{2^{n-1}}$$

Similarly, the three-way interaction of variables  $X_1$ ,  $X_2$ , and  $X_3$  is:

$$X_{123} \text{ Interaction} = \frac{\sum_{k=1}^{2^n} (X_{1k} X_{2k} X_{3k}) Q_{jk}}{2^{n-1}}$$

At this point it is easy to observe that, for a given interaction, multiplying the level codings for each interacting variable in trial will result in a level coding

---

<sup>29</sup> See Davies, Section 7.441, p. 262

vector corresponding to the interaction. Yate's method first calculates the level coding vectors for all interactions and then uses these vectors to compute main effects and interactions. These vectors are usually computed in "standard order" where all level coding vectors corresponding to the main effects and interactions of  $n-1$  variables are combined with the level coding vector of the  $X_n$  variable to determine the coding vectors of all interactions with the  $X_n$  variable. Thus, the order of computation is:

$$X_1, X_2, X_{12}, X_3, X_{13}, X_{23}, X_{123}, X_4, X_{14}, X_{24}, X_{124}, X_{34}, \dots$$

This algorithm effectively generates all distinct combinations of main effects and interactions. The total number of such calculations [Ref. 7, sec 24.11, p. 822] is:

$$\sum_{k=1}^n \binom{n}{k} = 2^n - 1$$

Consequently, an algorithm using this technique has complexity order  $O(2_n)$ .

## APPENDIX G. LISTING OF SENSITIVITY EXPERIMENT INPUTS

This appendix list the grouping of variables which comprise individual experiments in both the attack and defend scenarios. Code letters are used to correlate variable description with the results for each experiment. Input code identifies a particular input during data analysis

### Experiment 1: Single Inputs of Interest

## APPENDIX H. ESTIMATING RECALCULATION REQUIREMENTS

A consequence of the simultaneity within MOSCOW is that, by fixing input parameters and then successively recalculating the MOSCOW spreadsheet, model outputs converge to specific values. Although Romero [Ref. 1] proves MOSCOW's algorithms will converge, his explanation gives no information on the path this convergence takes or the points at which numerical limitations present computational difficulties<sup>30</sup>. Until this information is provided, model users face the problem of finding some reasonable way to estimate the number of recalculations required to move the point of output convergence of an initial set of input values to a new point defined by a specific change in these initial inputs. One way to approach this problem is to assume that, with no information to the contrary, the number of recalculations required to obtain convergence for changes in inputs which result in "small" changes of outputs is less than or equal to the number of recalculations need to produce convergence for those changes in inputs which produce "large" changes in outputs. With this idea, the

---

<sup>30</sup> The possibility exist that certain ranges of input values may not result in convergence as a result of excessive truncation, overflow, or underflow conditions which result from the inherent limitation of computers.

following heuristic approach was used to determine the number of recalculations required to produce a satisfactory level of convergence:

1. Double the numbers of Red forces while leaving all other inputs at a fixed level.
2. Recalculate the model 256 times. (Experience has shown this will produce convergence to at least 12 decimal places.)
3. Return Red force levels to their original values.
4. Perform 256 successive recalculations of the model, recording the resulting levels for those outputs of interest at each recalculation.
5. Assume that model outputs converge to the values obtained in the final recalculation.
6. Compute the difference between the output levels observed on each recalculation and those of the last recalculation.
7. Select as the recalculation requirement the number of recalculations which will guarantee convergence to within a desired amount.

For this investigation, the accuracy requirements defined in Section IV lead to the following calculations:

1. Attack Scenario Convergence Limit  
Since a Blue unit in the Attack scenario contains 369 combat vehicles, the accuracy requirement,  $A_{atk}$ , is:

$$\begin{aligned} A_{atk} &= (.5)(1/369) \\ &= 1.355 \times 10^{-3} \text{ Blue Units} \end{aligned}$$

2. Defense Scenario Convergence Limit

Since a Blue unit in the Defense scenario contains 1108 combat vehicles, the accuracy requirement,  $A_{\text{def}}$ , is:

$$\begin{aligned} A_{\text{def}} &= (.5)(1/369) \\ &= 4.513 \times 10^{-4} \text{ Blue Units} \end{aligned}$$

Performing the above heuristic procedure using the inputs for the Attack and Defend scenarios in Appendix B and comparing the resulting levels of convergence for both "Standing" and "Replacement" Blue unit outputs with the appropriate accuracy requirement leads to the conclusion that 21 recalculations achieve desired convergence in the Attack scenario while 15 suffice in the Defense. Figures 1-4 show the levels of convergence for these cases. Results of this procedure also indicate that MOSCOW's algorithm converges by oscillating about the limiting value for each output. While an interesting observation, this characteristic of convergence may not be true in general.

Figure 1 Convergence of Attack Scenario, Standing Blue Units Required.

Figure 2. Convergence of Attack Scenario, Replacement Blue Units Required.

Figure 3. Convergence of Defense Scenario, Standing Blue Units Required.

Figure 4. Convergence of Defense Scenario, Replacement Blue Units Required.

## APPENDIX I. FACTORIAL EXPERIMENT MACRO LISTING

The following listings are examples of those incorporated into the MOSCOW spreadsheet in order to perform factorial experiments. Two different, but essentially equivalent programs were used. This was necessary to overcome the LOTUS 1-2-3, ver 2, macro limitation on the number of nested loops which can be imbedded within a macro. This limitation restricts the efficiency of experiments using nine or more inputs.

Each macro has three elements. The first section contains variable declarations which specify the changes in levels of specific inputs. The next section contains a control section that implements a  $2^n$  factorial design as a series of nested loops. Recalculation of the spreadsheet is called by this section. The specific number of recalculations performed must be declared in the spreadsheet iteration counter prior to macro execution. Upon completion of the specified number of iterations for each trial, this section writes the results to a table which contains indicators of the levels for all experimental variables (inputs) and the resulting levels for five model outputs. One row of the results table corresponds to one trial of the experiment. A "1" in a column associated with a variable indicates that the input was at the high level during that

trial. Zeros indicate inputs at the low level. The last program section writes the results of each trial to an output file. Due to memory limitations, results were written in 128 record blocks. The output files GROUP1, GROUP2, ..., GROUP8 are the destinations of these results. These files must exist prior to macro execution.

# 1. MACRO listing for 10 variable experiment.

## APPENDIX J. INPUT SENSITIVITY PROGRAM LISTING

This APL program computes the main effects and levels of interaction for a sensitivity experiment using the LOTUS macro program in Appendix I. Lotus format output files must be merged and converted into a STATGRAPHICS file using the file conversion facilities within version 6.4. This program will read these files and interactively compute a results file which contains all resulting main effects and levels of interaction. Once results for a given experiment have been calculated, the results are saved for further analysis. The user is given the option of replaying results at user selected levels of significance or requesting a rank ordering of the magnitudes of all interactions and main effects. This ordering can be used to determine the dominance of main effects vice corresponding interactions.

## APPENDIX K. COMPUTED MAIN EFFECTS

The following tables contain the main effects for all inputs as computed from factorial experiments. Main effects for those inputs marked with an asterisk were used in comparisons with a priori predictions of how a small (10 percent) increase in input level should influence model output. All cases where such expectations do not agree with observation appear in instances where the main effect term is dominated by interactions with other inputs.
